Abstract—Recent research has indicated that the antimicrobial chemical triclocarban (TCC) represents a new type of endocrine disruptor, amplifying the transcriptional activity of steroid hormones and their receptors while itself exhibiting little affinity for these receptors. The effects of TCC were studied in the freshwater mudsnail *Potamopyrgus antipodarum*. Specimens were exposed to concentrations ranging from 0.05 to 10.5 $\mu\text{g/L}$ dissolved TCC and were removed and dissected, and embryos contained within the brood pouch were counted and classified as shelled or unshelled after two and four weeks of exposure. After four weeks, environmentally relevant TCC concentrations of 1.6 to 10.5 $\mu\text{g/L}$ resulted in statistically significant increases in the number of unshelled embryos, whereas 0.2, 1.6, and 10.5 $\mu\text{g/L}$ exposures significantly increased numbers of shelled embryos. The lowest observed effect concentration (LOEC) was 0.2 $\mu\text{g/L}$, the no observed effect concentration (NOEC) was 0.05 $\mu\text{g/L}$; the 10% effective concentration (EC10) and the median effective concentration (EC50) for unshelled effects were 0.5 $\mu\text{g/L}$ and 2.5 $\mu\text{g/L}$, respectively. Given the widespread occurrence of TCC in the environment and the effects shown at environmentally relevant concentrations, these results indicate that TCC may be causing reproductive effects in the environment. Furthermore, the present study indicates that environmental risk from a new class of endocrine-disrupting chemicals (EDCs) is both qualitatively and quantitatively similar to risk from existing classes of EDCs. Keywords—Emerging contaminants Reproduction Endocrine disruptors Personal care products Snails

INTRODUCTION

Many synthetic organic chemicals have been classified as endocrine-disrupting chemicals (EDCs) because of their ability to interact with and alter endocrine systems and cause adverse health effects in organisms or their offspring. In humans, there is evidence and concern that these chemicals may be contributing to various types of cancer [1,2], abnormal timing of the onset of puberty [3], and fetal abnormalities [4,5]. In wildlife, effects range from feminization, hermaphroditism, and intersexuality [6,7] to impacts on fertility and fecundity [8,9] to behavioral effects [10], and, in some cases, complete collapse of populations has been documented [11,12].

There is a large body of literature concerning EDCs with estrogenic or androgenic potential [13]. Many of these studies address the question of whether a single chemical alone acts as an endocrine disruptor, generally as an agonist or antagonist to one of the steroid hormone receptors but also through non-receptor mediated modes of action. New research suggests that the chemical triclocarban (TCC; Fig. 1), long suspected to interfere with reproduction in rats and rabbits [14], exhibits a novel form of endocrine disruption. Triclocarban alone exhibits little or no activity toward steroid hormone receptors but amplifies transcriptional activity of steroid sex hormones in the estrogen and androgen receptors, both in human cell lines [15]. In vivo, when added to a diet containing a high amount of

testosterone, it significantly increased male sex organ weight relative to control diets, or those diets containing testosterone or TCC alone in castrated rats [16].

Triclocarban was introduced to commerce in the United States in 1957 and has been routinely added to cosmetics and personal care products since then. Annual production in the United States is estimated at between 500,000 and 1,000,000 lbs (225,000–450,000 kg) per year [17]. Triclocarban is incompletely removed in wastewater treatment plants. Most of it partitions into sludge, but some is also discharged in effluent accompanying steroid hormones and other EDCs [18,19], causing a potential risk to aquatic organisms downstream. It is estimated to be detectable in 60% of U.S. streams, with mean and median concentrations of 213 and 109 ng/L, respectively [18].

Given its characteristics as a new kind of endocrine disruptor and its widespread occurrence in the aquatic environment, there is a need to determine whether TCC poses a demonstrated risk to aquatic species. The test species for these experiments is the freshwater mudsnail *Potamopyrgus antipodarum* (Gastropoda, Prosobranchia, Hydrobiidae), commonly called the New Zealand mudsnail, which has previously been used in a whole-organism bioassay for estrogenic and androgenic endocrine-disrupting effects [20]. Native to New Zealand, it was introduced to Europe in the mid-1800s [21] and to North America in the late 1980s [22]. Unlike its native range, where males are present and it reproduces sexually, in its invasive range the species is almost exclusively female and is ovoviparous and parthenogenetic [22].

The objectives of the present study are to determine whether environmentally relevant concentrations of TCC impact reproductive output in *P. antipodarum* and, if so, whether TCC

causes effects that are distinguishable from the effects of traditional estrogen receptor agonists *in vivo*. The hypothesis is that TCC will increase reproductive output in a dose-dependent manner. The reasoning behind this is that TCC acts by enhancing the transcriptional activity of endogenous estrogens present in the female, and this should lead to increased numbers of embryos within the brood pouch, as has been found in experiments with other exogenous estrogenic EDCs [23].

METHODS AND MATERIALS

Chemicals

Sea salt was obtained from Aquarium Pharmaceuticals. Calcium carbonate, sodium bicarbonate, reagent alcohol, acetonitrile, methanol, ethyl acetate, acetone, and acetic acid were all obtained from Fisher Scientific and were of the highest grade available. Triclocarban (3,4,4'-trichlorocarbanilide, 99% purity) was obtained from Aldrich. Deuterated triclocarban (TCC-d7) and carbon-13-labeled triclocarban ($[^{13}\text{C}_6]\text{TCC}$) were obtained from Cambridge Isotope Laboratories.

Experimental methods

Specimens of the freshwater mudsnail *P. antipodarum* were collected from Putah Creek near Winters, California, USA, on October 17, 2008 under the supervision of California Department of Fish and Game staff. Aquatic vegetation was collected in D-nets, and snails were removed and kept in river water in 1-gallon buckets for transfer to the laboratory. Within 2 h, snails were transferred into 10-gallon aquaria filled with artificial freshwater (Milli-Q water plus added salts at a rate of 5 g CaCO_3 , 5 g sea salt, and 0.5 g NaHCO_3 per 10 gallons of water).

After 3 to 5 d of acclimation to laboratory conditions, 60 individuals with shell lengths greater than 3.0 mm were transferred to each individual 1-L jar filled with 800 ml artificial freshwater. The jars were aerated through glass pipettes to keep dissolved oxygen near saturation.

Each jar was spiked with a solution of TCC dissolved in reagent alcohol to achieve five nominal target aqueous TCC concentrations (0.045, 0.14, 0.45, 1.4, 4.5, and 14.0 $\mu\text{g/L}$, in triplicate). Reagent alcohol always represented less than 0.003% of the final volume of solution. The control blank triplicates were also spiked with an equivalent volume of pure reagent alcohol. A pilot study was conducted that contained both water only and solvent controls, and results showed no significant differences in number of embryos between the treatments, suggesting that ethanol had no effect on embryo numbers. Therefore, no water-only control was used during the duration of this experiment. The pilot study also indicated that large amounts of TCC (i.e., >10% of the total mass in the jar)

were partitioned into the snail biomass within 5 d. To keep aqueous TCC concentrations relatively constant, water was replaced and respiked at the initial concentration level in each jar every 3 d.

The experiments were conducted at $14 \pm 0.7^\circ\text{C}$ under a light:dark rhythm of 16:8 h. Snails were fed ground TetraMin (Tetra) every day or every other day at an approximate rate of 0.1 mg/d. At $t = 0, 2,$ and 4 weeks, 15 specimens were removed from each jar and narcotized for 1 h in 2.5% MgCl_2 solution. Photographs of the specimens were taken, and the length of the shell was measured using image processing software. Shells were cracked in a vice, and dissection took place under a dissecting microscope. To measure reproductive output, embryos were counted, making a distinction between those with shells (i.e., older, more developed embryos) and those without (i.e., newer embryos). The identical procedure was performed at the same time points on 15 individuals that had been kept in 10-L aquaria and was repeated for snails kept in aquaria at 6 and 8 weeks as well. Mortality in the treatments was recorded every 3 d, and dead snails were removed.

All data were analyzed using JMP 8.0 (SAS Institute). Using absolute embryo numbers, means and standard errors were calculated, followed by one-way ANOVA ($n = 3$) and comparison of treatment means with the control using Dunnett's method ($\alpha = 0.05$). All ANOVA assumptions were verified through standard tests of residuals. Using percentage responses relative to the control, nonlinear regressions were calculated using a three-parameter logistic model and were used to calculate a 10% effective concentration (EC10) and median effective concentration (EC50) for each, where EC10 and EC50 are the concentrations causing a 10 and a 50% increase in embryo numbers relative to the solvent control, respectively. All effects are referenced to time-weighted mean concentrations as determined analytically rather than nominal concentrations.

Water chemistry

At day 1, 4, 10, 16, and 25, water samples were taken from one randomly chosen replicate of each of the exposure concentrations immediately before and shortly after the water renewal and respiking procedure. These samples were measured for dissolved oxygen and pH, then analyzed for dissolved TCC concentration. The pH was measured using a Mettler Toledo pH meter. Dissolved oxygen was measured using a YSI dissolved oxygen meter. At the same intervals, additional samples were taken to measure nitrite/nitrate and ammonia with Aquarium Pharmaceuticals test kits.

For determining dissolved TCC, samples were first acidified to pH 2 using hydrochloric acid. Deuterated surrogate (TCC-d7) was spiked into the samples, followed by solid-phase extraction. The extraction was carried out on Waters Oasis HLB 6-cc disposable cartridges on a Supelco Visiprep DL manifold. Each cartridge was conditioned with 5 ml 75:25 ethyl acetate/acetone mixture followed by 5 ml methanol and then 5 ml Milli-Q water. Samples of 10 ml were loaded at a rate of between 1 and 2 ml/min and then dried for 10 min at 40 mmHg. Cartridges were eluted with 8 ml of 75:25 ethyl acetate/acetone. Eluates were then evaporated to dryness under a gentle stream of nitrogen at 65°C . Finally, extracts were redissolved in 200 μl or 1 ml of

90:10 acetonitrile/Milli-Q water containing [$^{13}\text{C}_6$]TCC as an internal standard.

Extracts were analyzed via liquid chromatography with tandem mass spectrometry. Injection volume was 10 μl , and separation was achieved on a Phenomenex Prodigy ODS 100A 100×2.0 mm column at 40°C . The binary mobile phase consisted of 0.5 ml/min of 90:10 Milli-Q:acetonitrile with 2 mM acetic acid (A) and 50:50 methanol:acetonitrile with 10 mM acetic acid (B). The gradient was as follows: 20% B rising to 80% B over 16.5 min, then rising to 100% B over 2.5 min, followed by 1 min at 100% B. Detection was achieved using an Agilent (Santa Clara, CA) 1100 series LC/MSD ion trap with electrospray ionization in negative mode and multiple reaction monitoring. The drying gas flow rate was 12 L/min; the drying gas temperature was 350°C ; and the nebulizer pressure was 35 psi. All other instrument parameters were optimized for the detection of TCC.

The response was corrected by recovery of the surrogate TCC-d7 and normalized to the response of the internal standard [$^{13}\text{C}_6$]TCC. Calibration was via seven external standards, which were analyzed before and after every set of samples and the linear regression fit to the averages of each pair of responses. A summary of the chemicals analyzed is shown in Table 1. All data were analyzed using Bruker Daltonik DataAnalysis v.2.1 software.

RESULTS AND DISCUSSION

Dissolved oxygen was always above 95% saturation, and pH was 7.9 ± 0.4 . Nitrite, nitrate, and total ammonia were always below the detection limits of the tests, which were 0.1, 5, and 0.5 mg/L, respectively. Dissolved TCC concentrations decreased by 5 to 50% over the course of each 3- to 9-d period between analyses. The rate of disappearance decreased over each interval. Preliminary experiments indicated that significant amounts of TCC partitioned into snail biomass within days, so the decreasing rate of TCC disappearance is likely because the applied concentrations were approaching equilibrium with the TCC that had partitioned into the biomass of the snails. Even so, time-weighted mean concentrations in general showed good agreement with nominal concentrations; the concentrations (in micrograms per liter) were determined to be 0.05 (0.04 nominal), 0.22 (0.14), 0.47 (0.45), 1.6 (1.4), 4.1 (4.5), and 10.5 (14.0). The highest measured concentration (10.5) was probably lower than the nominal value (14.0) because of the insolubility of TCC in the alcohol stock or the water. Halden and Paull predict a solubility of TCC in water of 0.65 to 1.55 mg/L at 25°C [18]; however, the actual solubility is probably much lower, based on experience preparing aqueous

TCC solutions. In addition, this experiment was conducted at 14°C , at which the solubility would be expected to be lower than literature values referenced to 25°C . Calculated recoveries for the analytical procedure averaged 72%, with a standard deviation of 18%.

After two weeks of exposure, the number of embryos showed no significant differences from the controls. After four weeks, significant increases were found for numbers of unshelled, shelled, and total embryos, as shown in Figure 2. Exposures of 1.6, 4.1, and 10.5 $\mu\text{g/L}$ exhibited significantly elevated numbers of unshelled embryos, reaching 217% of the control numbers. Exposures of 0.2, 1.6, and 10.5 $\mu\text{g/L}$ resulted in significantly more shelled embryos, up to 167% of the control numbers. Total embryos were significantly greater than controls in snails exposed to 0.2, 1.6, 4.1, and 10.5 $\mu\text{g/L}$, up to 184% of the controls. The LOEC was therefore 0.2 $\mu\text{g/L}$, and the NOEC was 0.05 $\mu\text{g/L}$. The EC10 and EC50 for unshelled effects were 0.5 and 2.5 $\mu\text{g/L}$, respectively ($r^2 = 0.59$). The regressions did not show good fit with the unusual dose-response curves for shelled and total embryo numbers, so EC10 and EC50 were not calculated. The most logical reason why numbers of unshelled embryos showed the greatest increase is because, by four weeks, most if not all unshelled embryos have likely been formed since the start of the exposure and, therefore, best represent the effects of exposure conditions.

No effects on shell length were detected. Shell length was determined not to be a cofactor. If the exposures had been extended to six or eight weeks, it is possible that effects on embryo numbers would have been seen at even lower exposures, following the trend that was seen in a previous study [23]. Exposures were limited to four weeks for the sake of expedience and because preliminary experiments indicated that four weeks was sufficient to detect the effects. Mortality was less than 10% in all exposures except for one jar of 0.5 $\mu\text{g/L}$ and one jar of 4.1 $\mu\text{g/L}$, for which mortality reached 20 and 17% by the end of the four weeks, respectively. These jars had visible fungal growth on their bottoms at between three and four weeks, likely as a result of overfeeding, and this most likely led to higher mortality.

Embryo numbers in all treatments, including the controls, decreased substantially during the course of the experiment (see Fig. 3). Levels found in snails housed in the aquarium declined in a similar fashion, but at a slower rate. The results of a prior pilot experiment that took place several months earlier indicate a similar decline, suggesting that transferring the organisms to laboratory conditions caused their reproduction to slow during the course of the experiment. Anecdotal evidence from other laboratories suggests this to be a common effect of bringing wild-caught mudsnails into the laboratory.

Table 1. Selected analytical parameters

Chemical	Triclocarban	Deuterated triclocarban	^{13}C -labeled triclocarban
Purpose	Analyte	Surrogate	Internal Standard
Molecular wt	315.6	322.6	321.5
Precursor ion	313	320	319
Fragment	160	163	160
Instrument detection limit ($\mu\text{g/L}$)	0.35	0.10	n/a
Instrument quantitation limit ($\mu\text{g/L}$)	0.80	0.25	n/a
Limit of detection (ng/L)	10	2.9	n/a
Limit of quantitation (ng/L)	23	7.0	n/a

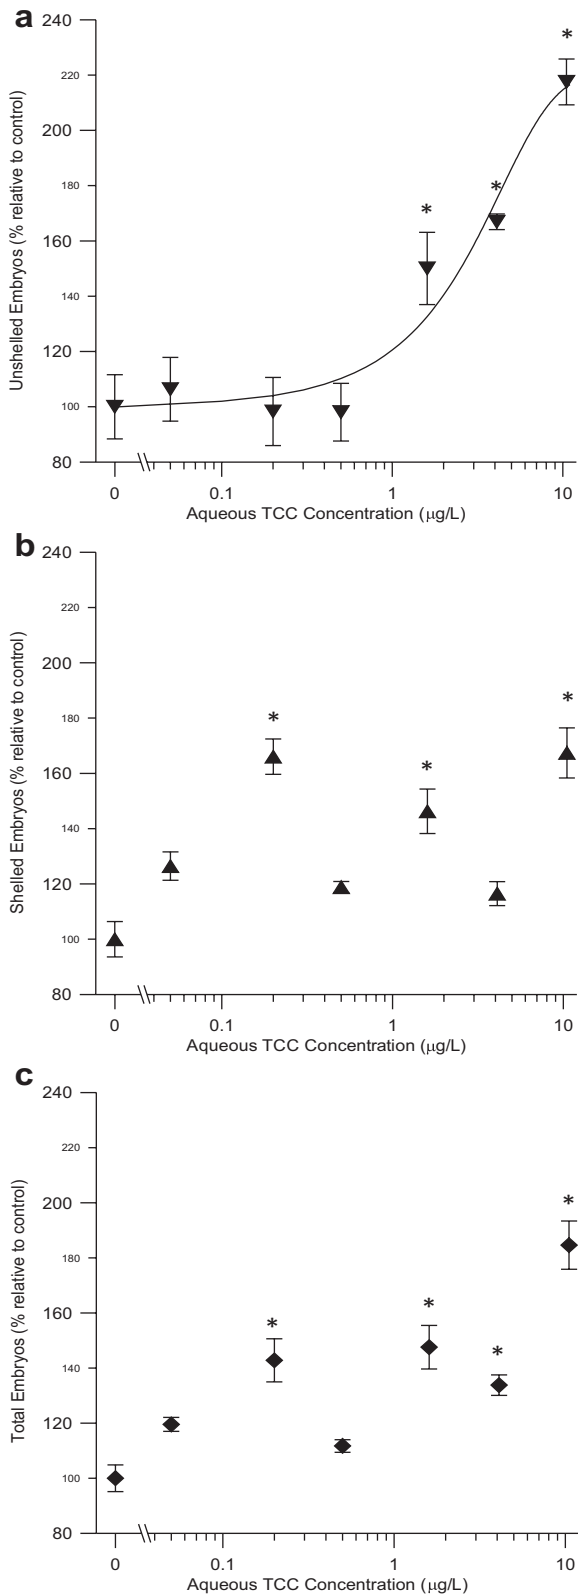

Fig. 2. Effects of dissolved triclocarban (TCC) exposures on embryo numbers of *Potamopyrgus antipodarum* at four weeks of exposure in percentage of the solvent control (mean \pm SEM, $n = 15$) for unshelled embryos (a), shelled embryos (b), and total embryos (c). The logistic regression line for unshelled embryos is shown. *Significantly greater than solvent controls at $p < 0.05$.

Fig. 3. Embryo numbers in the control and in an aquarium declined substantially over the duration of the experiment. The decline in the aquarium was slower and not as pronounced and leveled off at eight weeks.

The specific ecological impact of the effects seen in this experiment is not clear, but it is likely that, if the same effects are occurring in the environment, populations would be impacted. As Duft et al. [23] point out, increases in embryo production during seasonal minima in the reproductive cycle means more juveniles entering the environment at times when the environment is unfavorable for survival. Furthermore, limitations in the overall energy budget may then contribute to lower fecundity and lower survival rates in the seasonal maxima [23]. Multimonth exposures to examine effects of TCC on survival and multigenerational exposures to examine effects of populations in microcosms would enhance the understanding of the expected effects in the environment.

Although many studies have examined acute and chronic effects of TCC on aquatic organisms, few have found effects at such low levels. The NOEC for chronic toxicity to *Daphnia magna* has been reported at 0.5 to 1.0 $\mu\text{g/L}$. The most sensitive endpoint for TCC on aquatic organisms found in the literature is a NOEC of 0.101 $\mu\text{g/L}$ for decreased numbers of young in *Americamysis bahia*, a saltwater crustacean. The most sensitive study results for mollusks found in the literature were reduced viability (to 20% of control) in clam larvae at 10 $\mu\text{g/L}$ TCC and decreased larval length as low as 5 $\mu\text{g/L}$ [24], 50 times higher than the LOEC of 0.2 $\mu\text{g/L}$ found in the present study. Although TCC concentrations downstream of wastewater treatment plants have only rarely been found to be above 5 $\mu\text{g/L}$, levels above 0.2 $\mu\text{g/L}$ are quite common. It is estimated that 30 to 40% of samples described in the literature [18,25] are above the LOEC for the present study.

Others have found effects similar to those of the present study on embryo production in *P. antipodarum* when exposed to the known environmental estrogens bisphenol A (BPA), octylphenol (OP), nonylphenol (NP), and ethynylestradiol (EE2) in both sediment and water [20,23]. In water, the NOECs

have been determined to be 1 µg/L for BPA and OP and 5 µg/L for NP [20]. The mechanism of action (MOA) of TCC on *P. antipodarum* is not known, but it is possible that it acts similarly to experiments with the mammalian estrogen receptor in vitro [16], that is, amplifying the binding affinity and consequently increasing the transcriptional activity of naturally present estrogen to the estrogen receptor. However, some evidence indicates that estrogenic compounds act via a route different from binding to the vertebrate-like estrogen receptor in mollusks [26]. In fact, it is not clear at this point what the precise MOAs of estrogen analogues are in mollusks. Although the possibility exists that TCC shares a common MOA in mollusks with already identified estrogenic EDCs, molecular evidence from vertebrate studies suggest that the MOAs differ. If this is true, this experiment shows that chemicals with different mechanisms of action produce nearly identical results in vivo. It also highlights the need for both in vitro and in vivo studies, especially for chemical-by-chemical screening programs. In vivo studies may not distinguish between different mechanisms of EDC, whereas in vitro studies based on the current single chemical testing paradigm (e.g., Tier 1 of the U.S. Environmental Protection Agency's Endocrine Disruptor Screening Program) may miss potentially hazardous EDCs.

The present study represents a first step in characterizing risk to aquatic organisms of a new class of EDC. By showing that TCC, a chemical that exhibits little to no affinity for the estrogen receptor alone, causes reproductive effects that match those caused by known estrogen receptor agonists, the present study indicates that a chemical not addressed by the current paradigm in EDC screening methodologies can exhibit equally problematic environmental risk.
